(Received 7 April 2016; revised manuscript received 13 July 2016; published 11 October 2016)

We report on the quenching of single Ni adatom moments on Te-terminated Bi2Te2Se and Bi2Te3 topological insulator surfaces. The effect is noted as a missing x-ray magnetic circular dichroism for resonant $L_z$ transitions into partially filled Ni 3d states of theory-derived occupancy $n_d = 9.2$. On the basis of a comparative study of Ni and Fe using scanning tunneling microscopy and $ab$ initio calculations, we are able to relate the element specific moment formation to a local Stoner criterion. Our theory shows that while Fe adatoms form large spin moments of $m_s = 2.54 \mu_B$ with out-of-plane anisotropy due to a sufficiently large density of states at the Fermi energy, Ni remains well below an effective Stoner threshold for local moment formation. With the Fermi level remaining in the bulk band gap after adatom deposition, nonmagnetic Ni and preferentially out-of-plane oriented magnetic Fe with similar structural properties on Bi2Te2Se surfaces constitute a perfect platform to study the off-on effects of time-reversal symmetry breaking on topological surface states.

DOI: 10.1103/PhysRevB.94.161114

Three-dimensional topological insulators (TIs) are insulating in the bulk but host conductive topological surface states (TSSs), which follow a Dirac-like dispersion relation with spin and orbital momentum degrees of freedom chirally locked at a right angle [1,2]. As a consequence, currents with spin and orbital momentum degrees of freedom chiral states (TSSs), which follow a Dirac-like dispersion relation translating in the bulk but host conductive topological surface states of theory-derived occupancy $n_d = 9.2$. On the basis of a comparative study of Ni and Fe using scanning tunneling microscopy and $ab$ initio calculations, we are able to relate the element specific moment formation to a local Stoner criterion. Our theory shows that while Fe adatoms form large spin moments of $m_s = 2.54 \mu_B$ with out-of-plane anisotropy due to a sufficiently large density of states at the Fermi energy, Ni remains well below an effective Stoner threshold for local moment formation. With the Fermi level remaining in the bulk band gap after adatom deposition, nonmagnetic Ni and preferentially out-of-plane oriented magnetic Fe with similar structural properties on Bi2Te2Se surfaces constitute a perfect platform to study the off-on effects of time-reversal symmetry breaking on topological surface states.

In the search for model systems, local spin and orbital moment formation, magnetocrystalline anisotropy of 3d bulk and surface guest atoms, and charge doping were studied, particularly for prototypical bismuth chalcogenide TI host materials [5–8], where the nonvanished average exchange fields ($\mathcal{H}_\text{Ex}$) can be stabilized, e.g., by carrier-mediated exchange interactions $J_{2D/D}$ between guest atoms [9–11]. Dilute surface adatoms are promising since direct experimental access to structural and electronic properties using scanning tunneling microscopy (STM) and angle-resolved photoemission spectroscopy (ARPES) is retained. Here, ARPES reported intact TSSs [7], according to a simple picture of thermally fluctuating local moments ($J_{2D} \ll k_B T$) giving ($\mathcal{H}_\text{Ex}$) = 0 on the time scale required for a spin-flip process. In contrast, a recent low-temperature scanning tunneling spectroscopy (STS) study of local TSS scattering processes claims that paramagnetic but weakly coupled 3d adatom moments are able to locally produce exchange fields on transient time scales sufficient to gap the TI phase [12]. A full understanding is complicated by the presence of the adatoms’ nonmagnetic resonant scattering potential $U$, which, as in other Dirac materials such as graphene and $d$-wave superconductors, can counteract a moment-induced gap formation at the DP [13,14].

In this Rapid Communication we report on an efficient quenching mechanism of single Ni adatom moments on Te-terminated Bi2Te2Se and Bi2Te3 surfaces, despite a partially filled Ni 3d shell with occupancy $n_d = 9.2$. Our $ab$ initio calculations explain this surprising behavior in the framework of a local Stoner criterion, which predicts Fe adatoms to form large spin moments of $m_s = 2.54 \mu_B$ with out-of-plane
anisotropy, while Ni remains below an effective Stoner threshold for local moment formation. With the DP remaining in the Bi₂Te₂Se band gap for both elements Ni and Fe, these systems are ideal to study magnetism-dependent TSS-dominated transport, both macroscopically [15] and on the atomic scale via STS [12].

Our results are based on a thorough determination of the structural, electronic, and magnetic properties of Ni and Fe adatoms on Bi₂Te₂Se and Bi₂Te₃, combining local STM [16,17] with x-ray magnetic circular dichroism (XMCD) spectroscopy (X-Treme beamline, SLS [18]) and ARPES (SGM3 beamline at ASTRID2 synchrotron radiation facility [19]). Experiments were carried out with Bi₂Te₃ single crystals grown by the method described in Ref. [20] and with Bi₂Te₂Se single crystals identical to those used in Ref. [21]. For the latter crystals, four-point probe measurements have proven surface-dominated transport with a high bulk resistivity at low temperatures [15]. The crystals were cleaved in ultrahigh vacuum at room temperature using scotch tape, followed by cooling down to temperatures below 100 K within 25 min for ARPES, 20 min for XMCD, and within 5 min for STM measurements. Dilute amounts of Ni and Fe in the range of a percentage of a monolayer (ML, number of atoms per surface unit cell) were subsequently deposited from thoroughly outgassed and calibrated e-beam evaporators onto the cold substrate (T = 2 K for XMCD, T = 7 K for STM, and T ≈ 90 K for ARPES), in order to prevent clustering or subsurface diffusion of Ni and Fe atoms [22].

Figure 1(a) shows an STM topograph of the pristine Bi₂Te₃ surface after cleavage, which appears at the van der Waals bonds between the quintuple layers (QLs) (see the inset) leading to a Te-terminated surface. It shows the well-known defects in the Te layers of the topmost QL [23,24]. Similar studies on Bi₂Te₂Se crystals [see the Supplemental Material (SM) [25]] show 12% ± 3% of SeTe antisite defects in the surface Te layer. Apart from those infrequent SeTe defects, the sequence of the topmost two layers of Bi₂Te₃ and Bi₂Te₂Se is thus identical and we expect similar adsorption geometries and magnetic properties for the 3d atoms deposited on both Te-terminated substrates. Figure 1(b) shows the STM topograph after deposition of 1% ML Ni. In addition to the features from the intrinsic defects in the topmost Te layers (black circle), there is a statistical distribution of defects stemming from Ni adatoms which have an apparent height of 25–110 pm, depending on the bias voltage. Closer inspection reveals that the Ni atoms have two distinct appearances due to adsorption on either of the two hollow sites of the surface Te lattice [Fig. 1(c); see the lines]. Considering that the clover-shaped subsurface defects are attributed to Bi₆Te₄ antisites residing in the fifth layer (Te) of the first QL [24,26] and their position relative to the surface Te atoms (see the lines), we can assign the shallower Ni atom to Nihcp and the higher one to Nifcc. They have a strongly different relative abundance Nihcp : Nifcc of 0.2. For Fe on Bi₂Te₃, our STM experiments confirm the previously revealed hollow site adsorption, appearance in STM, and relative abundance Fehcp : Fefcc of 0.7 [8]. Very similar results are found for the adsorption of the two elements on Bi₂Te₂Se (not shown).

Density functional theory (DFT) calculations equivalent to those in Ref. [6]. We started from the two lateral positions of the adatoms revealed by STM [Fig. 1(c)] and then relaxed them [Fig. 1(d)]. While Nihcp strongly relaxes into the first Bi layer, Nihcp sits in the surface Te layer and pushes the underlying Bi atom downward. Using these two adsorption geometries, we calculate STM images [Fig. 1(e)] with the Tersoff-Hamann approach [27] by evaluating the partial charge density in a range of 0.4 eV below the Fermi energy (E_F) at ~2.1 Å above the surface. The images confirm the experimentally observed difference in height and appearance of Nihcp and Nifcc as well as the assignment to the adsorption sites. Our calculations for the case of Fe confirm previous results [8].

The top Te-Bi layer is identical for Bi₂Te₃ and Bi₂Te₂Se [see the structural models in Figs. 1(a) and 2(g) [28]], suggesting similar relaxed positions of Ni or Fe. As a consequence, we expect the same chemical bonding and magnetic properties for those substrates, as confirmed by x-ray photoemission spectroscopy (XPS) and XMCD results (see below).

Surface-sensitive XPS of the Bi 5d and Te 4d core levels from pristine Bi₂Te₂Se in Figs. 2(a) and 2(d) develop strong shoulders upon deposition of 0.4 ML Fe [Figs. 2(b) and 2(e)] and 0.5 ML Ni [Figs. 2(c) and 2(f)], while the Se 3d core
level spectrum does not show significant changes in the line shape (see SM [25]). This is consistent with metal adatoms residing between the two topmost layers, where they cause strong chemical shifts in neighboring Te and Bi atoms, but not in Se [see Fig. 2(g)], because adatoms have little influence on the third subsurface layer. Ni and Fe similarly shift Bi 5d (Te 4d) lines to lower (higher) binding energies, in accordance with the weakening of the polar Bi-Te bond toward a more metallic bonding, as expected. The peak decomposition (see SM [25] for details) shown in Fig. 2 reveals that, while Ni deposition generates a single component shifted by 0.46 eV, Fe undoubtedly forms two distinct components shifted by 0.23 and 0.72 eV with respect to the main pristine Bi doublet. Although coverages here are beyond the impurity regime, these two components are consistent with the STM results, which showed that Fe atoms sit directly above Bi atoms (hcp site, stronger chemical shift) and above empty spaces (fcc site, weaker chemical shift) with nearly equal probability. Ni atoms in contrast strongly prefer fcc sites leading to only one shifted component. The Te spectra in Fig. 2(b) show only one additional component in both cases Ni and Fe, very likely because both fcc and hcp adatoms are embedded in a Te triangular geometry.

In order to study the doping effect of adatoms on the TSS, we performed ARPES for different coverages. Generally, the surface impurities lead to a downward energy shift of the TSS and bulk bands [28], which saturates at coverages in the percentage range of a ML. This indicates electron transfer from the adatom to the substrate. As shown in Fig. 3, at \( \leq 1\% \) coverages, only the linearly dispersing TSS crosses \( E_F \) located in the bulk band gap of Bi\(_2\)Te\(_3\) and Bi\(_2\)Te\(_2\)Se. Thus, these systems represent the very particular case where transport will be determined exclusively by the interaction of the TSS with the localized 3d guest atom’s charge and magnetic moment, which will be investigated in the following.

The late 3d transition element Ni is known to be a borderline element for transitions between high-spin 3d\(^{4}\)s\(^{2}\) and low-spin 3d\(^{3}\)4s\(^{1}\) configurations already in the free atom case or on weakly interacting graphitic substrates [29,30], and thus adatom electronic and magnetic ground state configurations are highly sensitive to interactions with the host surface. For an analysis of the magnetic ground state properties on Bi\(_2\)Te\(_3\) and Bi\(_2\)Te\(_2\)Se, we performed x-ray absorption spectroscopy (XAS) at the L\(_{3,2}\) edges (Fig. 4), which provide information on the local electronic state, since the spectral shapes and resonant absorption intensities depend on the distribution of holes in the 3d shell. For magnetic contrast we applied large magnetic fields of \( B = 6.8\,\text{T} \) collinear to a positive (+) and negative (−) circularly polarized x-ray beam, as depicted in Fig. 4(a). Differences in the respective absorption spectra \( \sigma^+ \) and \( \sigma^- \) reflect the magnetic ground state of single 3d atoms as described in an earlier work [6]. Figures 4(a) and 4(b) summarize Ni and Fe spectroscopy in the single impurity limit and corresponding DFT results based on the spin-polarized relativistic multiple-scattering or Korringa-Kohn-Rostoker formalism using the coherent potential approximation [31], together with Fermi’s golden rule [32]. All XAS data in Fig. 4 were measured at normal incidence \( \theta = 0^\circ \) in the total electron yield mode, and spectra are shown after Bi\(_2\)Te\(_2\)Se background subtraction. Before and after XAS characterization, the samples were carefully checked for oxygen contamination using the XAS at the O K edge.

Prominent resonant multiplet structures visible especially at the leading L\(_3\) edge of Ni and Fe spectra are typical for partly filled localized d shells weakly hybridized with their environments. The well-resolved multiplet structures in XAS serve as a fingerprint of the local d-shell configurations and show an exceptional agreement with the ones derived from DFT [right panels of Figs. 4(a) and 4(b)]. They correspond to unfilled Ni and Fe d-shell occupancies \( n_d = 9.2 \) and \( n_d = 6.9 \), respectively. Strikingly, while Fe develops a local moment as reflected by the Fe XMCD signal (\( \sigma^+ - \sigma^- \)), Ni takes a nonmagnetic ground state [see the lower panels in Figs. 4(a) and 4(b)]. Corresponding spectroscopy data at a grazing incidence \( \theta = 60^\circ \) gave similar results for Ni, while Fe spectra showed a pronounced out-of-plane magnetic easy axis with a magnetic anisotropy of 7 ± 3 meV/atom (see SM [25]), in agreement with Eelbo et al. [8]. Consistently, our DFT results in local moments of \( m_L = 0\mu_B \) and \( m_J = 0\mu_B \) for Ni and \( m_L = 2.54\mu_B \) and \( m_J = 0.41\mu_B \) for Fe. The moments are determined mainly by the 3d shell since 4s and 4p contributions are negligible for Ni (\( m_{4s} = 0\mu_B \) and \( m_{4p} = 0\mu_B \)) and for Fe (\( m_{4s} = 0.026\mu_B \) and \( m_{4p} = 0.031\mu_B \)). This quenching of the Ni atomic moment is a consequence of the interaction of the 3d element with the top Te-Bi layer as the experimental finding is the same for binary Bi\(_2\)Te\(_3\) (see SM [25]).
To gain an understanding of the mechanism responsible for the local Ni moment quenching in a partially filled $3d$ shell, we compare the stability of the magnetic states of relaxed Ni and Fe atoms with our DFT calculations. The local densities of states (DOS) in Fig. 5 show that despite the localized character of the Ni and Fe $d$ electrons, the width of the partially occupied energy bands is rather large due to hybridization with the electronic states of the surrounding host atoms and is comparable to the width of the energy bands in 3$d$ itinerant ferromagnets. This result suggests the use of the Stoner criterion ($I\chi_0^k \geq 1$) for the spontaneous formation of a spin moment on atom $k$ (Ni or Fe in our case), where $(I\chi_0^k)$ is the so-called Stoner product to analyze the atom of type $k$. For the most simple situations, $(I\chi_0^k)$ can be split into the Stoner integral $I^k$ and the enhanced spin susceptibility $\chi_0^k = 2\mu_B n^k(E_F)$, where $n^k(E_F)$ is the DOS at $E_F$. For the more general case of an alloy and adatoms considered here, we express $(I\chi_0^k)$ using linear response theory, as suggested by Deng et al. [33] (see SM [25]).

For Fe atoms, our self-consistent calculations give a Stoner product $(I\chi_0)^{Fe} = 2.68$ well above 1, while for Ni we find only $(I\chi_0)^{Ni} = 0.78$. We thus can understand the quenching mechanism on the atomic level surprisingly well within the Stoner model, triggered by a critically low DOS at $E_F$ on the Ni site close to the edge of the Ni $d$ band (Fig. 5).

In summary, we report on the complete quenching of Ni adatom moments situated on Te-terminated bismuth chalcogenide topological insulator surfaces. Comparing the adatom site and electronic properties of Ni with magnetic Fe, our study provides a clear understanding of the quenching in the framework of a local Stoner theory. We find Fermi levels in the gap of Bi$_2$Te$_2$Se in the presence of adatoms, which are ideal for investigating topological insulators under nonmagnetic Ni and out-of-plane Fe moment perturbations. Under such well-defined magnetic off/on conditions, the recently claimed gap opening solely due to nonmagnetic resonant scattering potentials [34] can be verified using surface concepts.
